Severe spinal cord injury in humans leads to a progressive neuronal dysfunction in the chronic stage of the injury. This dysfunction is characterized by premature exhaustion of muscle activity during assisted locomotion, which is associated with the emergence of abnormal reflex responses. Here, we hypothesize that undirected compensatory plasticity within neural systems caudal to a severe spinal cord injury contributes to the development of neuronal dysfunction in the chronic stage of the injury. We evaluated alterations in functional, electrophysiological and neuromorphological properties of lumbosacral circuitries in adult rats with a staggered thoracic hemisection injury. In the chronic stage of the injury, rats exhibited significant neuronal dysfunction, which was characterized by co-activation of antagonistic muscles, exhaustion of locomotor muscle activity, and deterioration of electrochemically-enabled gait patterns. As observed in humans, neuronal dysfunction was associated with the emergence of abnormal, long-latency reflex responses in leg muscles. Analyses of circuit, fibre and synapse density in segments caudal to the spinal cord injury revealed an extensive, lamina-specific remodelling of neuronal networks in response to the interruption of supraspinal input. These plastic changes restored a near-normal level of synaptic input within denervated spinal segments in the chronic stage of injury. Syndromic analysis uncovered significant correlations between the development of neuronal dysfunction, emergence of abnormal reflexes, and anatomical remodelling of lumbosacral circuitries. Together, these results suggest that spinal neurons deprived of supraspinal input strive to re-establish their synaptic environment. However, this undirected compensatory plasticity forms aberrant neuronal circuits, which may engage inappropriate combinations of sensorimotor networks during gait execution.

Keywords: spinal cord injury; neuronal dysfunction; exhaustion of locomotor activity; compensatory plasticity; syndromic analysis

Abbreviation: SCI = spinal cord injury

Introduction

More than half of human spinal cord injuries lead to permanent paralysis below the level of the injury, as well as severe bladder, bowel, sexual and immune dysfunction (Fawcett et al., 2007; Rieger et al., 2009). There is overwhelming evidence that the dramatic consequences of a severe SCI expand beyond these apparent deficits (Hiersenzenz et al., 2000; Dietz and Muller, 2004; Calancie et al., 2005; Courtine et al., 2009; Dietz et al., 2009; Boulenguez et al., 2010; Murray et al., 2010; Horst et al., 2012). Various
electrophysiological studies have suggested that neuronal circuits deprived of supraspinal input undergo a progressive and extensive remodelling (Calancie et al., 1996, 2000; Maegle et al., 2002; Beres-Jones et al., 2003; Calancie et al., 2005; Harkema, 2008); a process that continues to evolve for years after the SCI (Dietz, 2010). These alterations have been associated with the development of neuronal dysfunction in chronically paralysed individuals. This clinical syndrome is characterized by premature exhaustion of the overall motor neuronal output and poorly coordinated muscle activation patterns during assisted stepping on a treadmill (Dietz and Muller, 2004; Dietz et al., 2009).

Restoration of motor function after severe SCI has been interpreted as the need to regenerate severed fibres to their original target (Tuszynski and Steward, 2012). However, the progressive neuronal dysfunction observed in paralysed individuals emphasizes that recovery of useful sensorimotor capacities after severe SCI will rely on the ability to design interventions that will additionally preserve the integrity of neuronal networks caudal to the injury (Dietz, 2010; Roy and Edgerton, 2012).

A deeper understanding of the mechanisms leading to neuronal dysfunction after severe SCI may contribute to conceptualizing therapeutic strategies capable of counteracting the development of neuronal dysfunction. Various studies in experimental animals uncovered a mosaic of injury-induced molecular and cellular changes in segments caudal to a SCI (Krenz and Weaver, 1998; Ballermann and Foud, 2006; Kitzman, 2006, 2007; Soares et al., 2007; Hou et al., 2008; Tan et al., 2008; Hou et al., 2009; Boulenguez et al., 2010; Murray et al., 2010; Ichiyama et al., 2011; Singh et al., 2011; Kapitza et al., 2012; Tan et al., 2012). Depending upon the SCI model and specific functional assessments, these alterations in the properties of neuronal circuits have alternatively been classified as beneficial or detrimental. Therefore, the general impeding biological principles through which the development of neuronal dysfunction occurs remain unclear.

Although previous studies reported contrasting and variable conclusions, they consistently highlighted the progressive upregulation of receptor (Murray et al., 2010), synapse (Kitzman, 2006; Ichiyama et al., 2011; Kapitza et al., 2012; Tan et al., 2012), and fibre density (Krenz and Weaver, 1998; Ballermann and Foud, 2006; Hou et al., 2008, 2009) in response to the interruption of supraspinal input. Likewise, ablation of afferent pathways in the brain provokes the formation of new fibre arborizations and spines in the affected region (Kirov and Harris, 1999). This compensatory mechanism has been described as homeostatic plasticity (Turigiano et al., 1998), a process that strives to maintain the number and strength of synaptic inputs within denervated neuronal circuits. After incomplete SCI that leaves residual motor capacities, activity-dependent mechanisms steer compensatory plasticity in order to restore useful functional capacities (Raineteau and Schwab, 2001; Weidner et al., 2001; Edgerton et al., 2004; Courtine et al., 2008; Rosenzweig et al., 2010). In contrast, more severe SCIs impair the ability to produce movements, which prevents activity-dependent mechanisms from contributing to the remodelling of denervated neuronal networks in a useful direction. The resulting undirected compensatory plasticity may potentially lead to detrimental changes in neuronal circuit properties.

To test this hypothesis, we developed a new rodent model of SCI (Courtine et al., 2008; van den Brand et al., 2012) that replicated the key characteristics of neuronal dysfunction observed in severely paralysed human subjects. Using a range of multifaceted assessments and novel syndromic analysis (Ferguson et al., 2013), we provide evidence suggesting that undirected compensatory plasticity contributes to the development of neuronal dysfunction in the chronic stage of severe SCI.

**Materials and methods**

**Experimental setup**

Experiments were conducted on adult female Lewis rats (~220 g body weight). Animals were housed individually on a 12 h light/dark cycle, with access to food and water ad libitum. Temperature (22 ± 1°C) and humidity (40–60%) in the animal facilities were maintained constant in accordance to Swiss regulations for animal housing. All animals were handled daily for at least 2 weeks before the first surgeries. Animal care, including manual bladder voiding, was performed twice daily throughout the post-injury period. All procedures and surgeries were approved by the Veterinary Office of the cantons of Zurich and Vaud, Switzerland.

**Surgical procedures and post-surgical care**

All surgical procedures used have been described previously (Courtine et al., 2009; Musienko et al., 2011). Under aseptic conditions and general anaesthesia, a partial laminectomy was performed over spinal segments L2 and S1. Stimulating electrodes were created by removing a small piece (~1 mm notch) of insulation from Teflon-coated stainless steel wires (AS632, Cooner Wire), which were subsequently secured at the midline overlying spinal level L2 and S1 by suturing the wires to the dura. A common ground wire (~1 cm of Teflon removed at the distal end) was inserted subcutaneously over the right shoulder. Bipolar intramuscular EMG electrodes, using the same wire type, were inserted bilaterally in the medial gastrocnemius and tibialis anterior muscles. All electrode wires were connected to a percutaneous amphenol connector (Ommetronics Connector Corporation) fixed to the skull of the rat. Analgesia (buprenorphine Temgesic®), ESSEX Chemie AG, 0.01–0.05 mg per kg, subcutaneous) and antibiotics (Baytril®, Bayer Health Care AG, 5–10 mg per kg, subcutaneous) were provided for 5 days post-surgery. After the completion of pre-injury recordings, a second surgery was performed. Partial laminectomies were made at mid-thoracic levels and two lateral hemisections were placed on opposite sides at the T7 (left) and T10 (right) spinal segments. This SCI completely interrupted all direct supraspinal input. The completeness of spinal cord lesions was verified histologically post-mortem.

**Kinematic, kinetic and electromyography recordings**

The same rats (n = 11) participated in kinematic, kinetic and EMG recordings before injury, and 1 week (subacute SCI) as well as 9 weeks (chronic SCI) after injury. Stepping capacities were recorded on a motorized treadmill belt set at a constant speed of 9 cm/s. Animals wore a custom-made jacket especially designed for either bipedal or quadrupedal locomotion (Dominici et al., 2012) that was connected to an automated, servo-controlled body-weight support system (Robomedica Inc). The optimal amount of body weight support...
was determined visually. Spontaneous (no facilitation) stepping capacities were recorded for both quadrupedal and bipedal postures, before injury as well as 1 and 9 weeks post-injury. To evaluate the functional capacities of lumbar spinal circuits in paralyzed rats, we applied an electrochemical neuroprosthesis that transformed lumbar spinal circuits from non-functional to highly functional networks (Courtine et al., 2009; Musienko et al., 2011, 2012; van den Brand et al., 2012). Chemical stimulations consisted of a systemic administration of the 5-HT2A receptor agonist quipazine (0.2–0.3 mg per kg, intraperitoneal) and the 5-HT1A receptor agonist 8-OHDPAT (0.05–0.3 mg per kg, subcutaneous). The agonists were injected 5 min before behavioural testing. Epidural electrical stimulations (0.2 ms duration, 100–500 µA, 40 Hz) consisted of continuous series of rectangular pulses delivered at 40 Hz over spinal segments L2 and S1 through the chronically implanted electrodes. To evaluate the capacity of lumbar spinal circuits to sustain stepping in the chronic stage of SCI, locomotor output was recorded every 7 min in a separate group of rats (n = 4) during a bout of continuous stepping (14 min) enabled by electrical epidural stimulation alone. In this condition no chemical stimulations were delivered in order to avoid time-dependent effects of pharmacological agents.

Kinematic, kinetic and electromyography analyses

All procedures used have been detailed previously (Courtine et al., 2009; Musienko et al., 2011; van den Brand et al., 2012). Kinematics of hindlimb stepping were captured by the high speed motion capture system Vicon (Vicon Motion Systems), consisting of 10 infrared cameras (MX-3+, 200 Hz). Reflective markers were attached bilaterally at the iliac crest, the greater trochanter (hip joint), the lateral condyle (knee joint), the lateral malleolus (ankle), the distal end of the fifth metatarsophalangeal joint and the tip of the fourth toe. The body was modelled as an interconnected chain of rigid segments, and joint angles were generated accordingly. Vertical ground reaction forces were recorded using a biomechanical force plate (2 kHz; HE6X6, AMTI) located below the treadmill belt. EMG signals (2 kHz) were amplified, filtered (10–1000 Hz bandpass), stored and analysed offline to compute the amplitude, duration and timing of individual bursts. For both the left and right hindlimbs, 10 successive step cycles were extracted from a continuous sequence of stepping on a treadmill for each rat under each condition. A 10-s interval was used when no or very minimal stepping movements were observed. A total of 147 parameters quantifying gait, kinematics, kinetics and EMG features were computed for each limb and gait cycle according to methods described in detail previously (Courtine et al., 2008, 2009; Musienko et al., 2011; van den Brand et al., 2012).

Electrophysiological experiments

Spinal reflexes were assessed in fully awake rats (n = 10). During testing, the animals were suspended in the air (no contact with the ground) using the trunk harness and robotic systems described above. To elicit reflexes, we delivered single rectangular pulses (0.5 ms duration) through the chronically implanted S1 electrode at 0.2 Hz. Before the injury, we identified the stimulus intensity (typically ~160–200 µA) that elicited the largest monosynaptic responses in the absence of direct muscle responses (direct stimulation of the motor nerve, equivalent to M waves), typically 1.5 to 2-fold above motor threshold (Gerasimenko et al., 2006), and used this intensity to test reflexes at 1 and 9 weeks post-injury. The compound motor-evoked potentials were recorded in both left and right tibialis anterior muscles (10 kHz), and the onset latency, peak-to-peak amplitude, and integral of the averaged (n = 5) reflex responses were determined.

Tracing procedures

Under general anaesthesia, a laminectomy over L1–L2 spinal level was performed to expose the dorsal aspect of the spinal cord. In a subset of rats with chronic SCI (n = 6), a 10% suspension of tetracetyldihydroxy-damine-conjugated dextran 3000 MW (TMR) (Invitrogen AG) was stereotactically injected into the spinal cord, using a 33 G needle on a 10 µl Hamilton syringe (1701 RN, Hamilton Company) attached to an UltraMicroPump (World Precision Instruments). Six injections of 200 nl TMR separated by 700 µm were performed in each hemicord. The injection coordinates were 800 µm lateral of the midline and ~700 µm above the ventral surface of the spinal cord.

To elicit locomotor-related expression of c-fos, the remaining chronic SCI rats (n = 5) stepped bipedally on a treadmill during 45 min with the electrochemical neuroprosthesis. Rats were returned to their cages and perfused exactly 60 min after stepping (Ichiyama et al., 2008; Courtine et al., 2009). All animals were deeply anaesthetized by an intraperitoneal injection of 0.5 ml pentobarbital-Na (50 mg/ml) and transcardially perfused with ~80 ml Ringer’s solution containing 100 000 IU/l heparin (Liquemin, Roche) and 0.25% NaNO2 followed by 300 ml of cold 4% phosphate buffered parafomaldehyde, pH 7.4 containing 5% sucrose. The brain and spinal cord were removed and postfixed overnight in the same fixative before they were transferred to 30% sucrose in phosphate buffer for cryoprotection. The tissue was embedded in Tissue Tek O.C.T (Sakura Finetek Europe), frozen at ~40°C, and cut to a thickness of 30 or 40 µm.

Immunohistochemistry

Mounted or free-floating sections were washed three times in 0.1 M PBS and blocked in 5% normal goat serum containing 0.3% Triton. For c-fos and neurofilament stainings, slices were pretreated with H2O2 and cold methanol (100%), respectively. Sections were then incubated in primary antibody diluted in the blocking solution overnight at 4°C (c-fos) or room temperature (neurofilament, vGlut1, vGlut2). TMvisualization incubation time was 48 h at 4°C. The primary antibodies used were rabbit anti-c-fos (1:5000; Santa Cruz Biotechnology) and anti-TMR (1:200; Molecular Probes, Life Technologies), mouse anti-neurofilament (1:10 000; Millipore) and anti-vGlut2 (1:5000; Millipore), and guinea pig anti-vGlut1 (1:2000; Millipore) antibodies. Sections were again washed and postfixed overnight in the same fixative before they were transferred to 30% sucrose in phosphate buffer for cryoprotection. The tissue was embedded in Tissue Tek O.C.T (Sakura Finetek Europe), frozen at ~4°C, and cut to a thickness of 30 or 40 µm.

Neuromorphological evaluations

TMR-labelled fibres and c-fos-positive neurons were counted using image analysis software (Neurolucida, MicroBrightField) on 4–5 transverse slices per animal. For TMR-labelled fibres, a rectangular grid half the size of the ventral horn was overlaid and intersecting fibres within the grey matter were counted. C-fos-positive neurons were quantified when no or very minimal stepping movements were observed. A total of 147 parameters quantifying gait, kinematics, kinetics and EMG features were computed for each limb and gait cycle according to methods described in detail previously (Courtine et al., 2008, 2009; Musienko et al., 2011; van den Brand et al., 2012).
Principal component analysis

To evaluate the characteristics underlying stepping for the different experimental conditions, we implemented a multi-step statistical procedure based on principal component analysis (Courtine et al., 2009; Musienko et al., 2011; Dominici et al., 2012). The various steps, methods, typical results, and interpretation of the analysis are detailed in Figs 2 and 3. The same procedure was applied for the syndromic analysis; all the collected kinematic, kinetic, EMG, electrophysiological, neuromorphological and immunohistochemical parameters of SCI animals \( n = 6 \) were manually curated and combined in a single matrix.

Comparisons with neuronal dysfunction in humans with severe injury

Electrophysiological recordings of leg muscle activity and spinal reflex behaviour were conducted in individuals with motor complete (Dietz et al., 2009; Hubli et al., 2012) or motor incomplete SCI (Hubli et al., 2012). To evaluate the capacity of spinal neuronal networks to sustain locomotion, we recorded the EMG activity of the tibialis anterior and medial gastrocnemius muscles during 10–15 min of robotically assisted stepping at a constant speed of 2.0 km/h and 65–75% body weight support. Spinal reflex behaviour was assessed in healthy subjects, as well as in spinal cord injured individuals in the early and late stage of SCI. Non-noxious electrical stimuli were randomly applied to the distal part of the tibial nerve in subjects wearing a harness in an upright, unloaded position, as performed in the rats. Each stimulation was composed of a series of eight biphasic rectangular stimuli with 2 ms single stimulus duration and a frequency of 200 Hz. Stimulation intensity was set at two times motor threshold. Reflex responses were recorded from the ipsilateral tibialis anterior muscle.

Statistical procedures

All data are reported as mean values ± SEM. Statistical evaluations were performed using one-way ANOVA for neuromorphological evaluations, and one- or two-way repeated-measures ANOVA for functional assessments. The post hoc Tukey’s or Fisher LSD test was applied when appropriate. Pearson’s correlation coefficients were used to evaluate univariate correlations, except for patient data where the Spearman’s rank correlation coefficient was computed. The significance level was set as IR value > 0.45 and \( P < 0.05 \), respectively.

Results

Staggered hemisection injury leads to complete and permanent paralysis

Adult rats received a severe SCI consisting of a left lateral hemisection at T7 and right lateral hemisection at T10, which interrupted all the direct supraspinal input to lumbosacral circuits (van den Brand et al., 2012). To test the functional impact of the SCI, we positioned the rats bipedally and quadrupedally on a motorized treadmill (9 cm/s) with robot-assisted vertical support (% of body weight support). In both postures, the rats showed continuous dragging of both hindlimbs along the treadmill belt, which was associated with the absence of EMG activity in flexor and extensor muscles of the ankle (Fig. 1B and C). Occasionally, some of the tested rats exhibited spontaneous hindlimb oscillations, either unilateral or bilateral, which rapidly extinguished after a few cycles, as previously observed in rats with complete SCI (Courtine et al., 2009).

Staggered hemisection injury leads to neuronal dysfunction in the chronic stage

We sought to evaluate the functional properties of lumbosacral locomotor circuits in the subacute (1 week post-injury) and chronic stage (9 weeks post-injury) of the SCI \( n = 9 \). To enable locomotion of the paralysed hindlimbs, we applied an electrochemical neuroprosthesis that transformed lumbosacral circuits from non-functional to highly functional networks (Courtine et al., 2009; Musienko et al., 2012). By increasing the general level of spinal excitability, this electrochemical spinal neuroprosthesis enables sensory information to become a source of control for stepping. In consequence, the recorded motor patterns were exclusively generated within lumbosacral circuits, without contribution from supra-lesional input (Courtine et al., 2009; van den Brand et al., 2012). As early as 1 week post-lesion, electrochemical stimulations promoted coordinated locomotion with appropriate timing of left and right limb alternation, and reciprocal activation between flexor and extensor muscles (Fig. 1A and B). In striking contrast, the same rats exhibited highly variable stepping patterns with poor inter- and intra-limb coordination in the chronic stage of the SCI (Fig. 1C).

We next aimed at quantifying gait performance pre-injury, and at the subacute and chronic stages of SCI. To achieve this, we applied a multi-step statistical procedure based on principal component analysis. We first conducted detailed kinematic, kinetic and EMG recordings, which allowed the computation of a large number of variables \( n = 147 \) that provided a comprehensive quantification of gait patterns for each rat and time point. Principal component analysis creates new variables that linearly combine the original parameters in order to maximize the amount of explained variance per principal component analysis. Individual gait cycles can be represented in the new de-noised space defined by the first three principal component analyses. Gait patterns associated with each experimental time point emerged in distinct spatial locations (Fig. 2A). To visualize these differences, we applied a least square elliptical fitting on each cluster. The distance between data points in the principal component analysis space provides a measure of the degree of discrepancy or similarity between the clusters, i.e. gait patterns (Fig. 2B). The dispersion of data points accounts for the variability of gait patterns within each rat and time point (Fig. 2B). This analysis revealed that gait patterns recorded in the chronic stage significantly
differed from \( P < 0.01 \), and showed a high gait variability compared with \( P < 0.05 \) those observed in the same rats pre-injury and in the subacute stage \( (n=9) \). Principal component analysis scores indicate the location of data points and conditions along each individual principal component analysis axis (Fig. 2C). Here, extraction of scores revealed that PC1 captured differences across the time points \( P < 0.001 \), whereas PC2 distinguished the subacute stage from the other time points \( P < 0.01 \). Next, we computed the factor loadings, which correspond to the correlation between each variable and each principal component analysis. We then identified variables with significant factor loading \( |\text{value}| > 0.5, P < 0.05 \), which we regrouped into functional clusters that we named for clarity (Fig. 3A). To provide a more classical representation of differences between time points, histogram plots were generated for the most prominent variable (highlighted within yellow frames; Fig. 3A) per extracted functional cluster in PC1 (Fig. 3B) and PC2 (Fig. 3C). This multi-step analysis showed that in the chronic stage of the SCI rats exhibited highly variable gait patterns, a pronounced flexed posture, poor interlimb coordination, altered distal joint control, and enhanced extensor muscle activation during electrochemically-enabled locomotion (PC1 clusters; Fig. 3B). Instead, slow movement, low level of weight bearing, and prolonged swing duration characterized gait patterns underlying stepping in the subacute stage (PC2 clusters; Fig. 3C). Together, these results not only emphasize the dramatic degradation of stepping capacities in the chronic stage of SCI, but also identify the ensemble of gait features that characterizes the syndromic signature of this neuronal dysfunction. We sought to leverage this detailed evaluation to decipher putative mechanisms underlying these functional changes.

Figure 1 The staggered lateral hemisection SCI led to deterioration of locomotor function in the chronic stage. (A) Diagram of the electrochemical neuroprosthesis. Rats were positioned bipedally over a moving treadmill belt and provided with body weight support. A representative locomotor trial of the same rat performed before injury (intact), (B) 1 week (subacute SCI) and (C) 9 weeks post-injury (chronic SCI) is shown. Above each panel, the % of body weight support is indicated and a stick diagram decomposition of hindlimb motion is shown together with colour-coded trajectories of hindlimb endpoints. Vectors represent the direction and intensity of the hindlimb endpoint velocity at swing onset. The corresponding sequences of hindlimb oscillations, raw EMG activity of an extensor (MG, medial gastrocnemius) and a flexor (TA = tibialis anterior) muscle and vertical ground reaction forces (vGRF) are shown below. Grey and red bars indicate the duration of stance and drag phases, respectively. For each time point, a polar plot representation illustrates the coordination between the oscillations of left and right hindlimbs (black line, single gait cycle; red arrow, average of all gait cycles). The density plot displays the coordination between the antagonistic muscles tibialis anterior and medial gastrocnemius throughout one locomotor trial. L-shaped patterns reflect perfect reciprocal activation of muscles.
Staggered hemisection injury leads to premature exhaustion of locomotor muscle activity

Chronically injured, non-ambulatory SCI patients showed premature exhaustion of leg muscle activity during robotically assisted locomotion (Fig. 4C; adapted from Dietz et al., 2009). We tested whether rats with a severe, chronic SCI exhibited a similar decrease in hindlimb muscle activation during electrically enabled stepping (Fig. 4A). At the onset of stepping, the electrical neuroprosthesis promoted coordinated locomotor movements with alternation between powerful bursts of EMG activity in flexor and extensor muscles. The recruitment of hindlimb muscles rapidly declined over time, and eventually reached amplitudes that were too low to sustain locomotion ($P < 0.05$; Fig. 4B). Similar exhaustion of locomotor EMG was observed during manually assisted movements in rats (data not shown). These results show that, as observed in humans, rats exhibited premature exhaustion of the overall locomotor muscle output in the chronic stage of a severe SCI.

Staggered hemisection injury leads to the emergence of abnormal long-latency reflex responses

In severely paralysed humans, exhaustion of locomotor muscle activity occurred in parallel with the emergence of abnormal, long-latency reflex responses in leg muscles (Dietz et al., 2009). To elicit these reflexes, a train of stimuli was applied to the tibial nerve in upright and unloaded human subjects. In the absence of neurological impairments, the stimulation evoked a short-latency (75–100 ms) reflex response in the ipsilateral tibialis anterior muscle (Fig. 5A). Reflex responses with similar latency but markedly reduced amplitude were recorded in the subacute stage of the injury (2 months post-SCI). Chronic, non-ambulatory SCI patients showed a diminished or nearly absent, early reflex response, and concurrently developed an abnormal, long-latency reflex response (200–300 ms) (Fig. 5A). The relative amplitude of this long-latency reflex response inversely correlated with locomotor capacities (Fig. 5E).

We investigated whether similar changes in hindlimb reflex responses occurred in severely paralysed rats. Before the SCI, electrical stimulation delivered through the S1 epidural electrode in fully awake rats elicited two well-defined reflex responses in the tibialis anterior muscle (Fig. 5B), which engaged a monosynaptic and a polysynaptic neural circuit (Gerasimenko et al., 2006). As previously described (Lavrov et al., 2006), the polysynaptic response corresponds to the short latency reflex response evoked in humans. In the subacute stage of the SCI, the polysynaptic response was either markedly reduced or completely suppressed (Fig. 5B). The same rats tested in the chronic stage of the SCI displayed a new, long-latency reflex response in the tibialis anterior muscle (25–50 ms, $P < 0.001$; Fig. 5B and C). Although epidural electrical stimulation primarily recruits afferent fibres (Courtine et al., 2009; Musienko et al., 2012), including the tibial nerve, these responses might not be completely equivalent to those observed in humans. As previously described in human patients, however, the amplitude of this abnormal long-latency
reflex response inversely correlated with locomotor capacities in rats ($r = 0.66$, $P < 0.05$; Fig. 5D).

**Staggered hemisection injury triggers extensive reorganization within denervated neuronal networks**

We surmised that the neuronal dysfunction syndrome, characterized by degradation of stepping capacities, premature EMG exhaustion and abnormal reflex responses, was in part due to abnormal rewiring of the denervated lumbosacral networks. To test this hypothesis, we first assessed putative changes in overall fibre density in spinal segments caudal to the SCI (Fig. 6A). Evaluation of neurofilament staining at spinal segment L4 revealed a 28% decrease in fibre density in intermediate and ventral laminae in the subacute phase compared with intact rats ($P < 0.001$; Fig. 6B). After the complete interruption of supraspinal pathways, severed axons show a rapid Wallerian degeneration (Hausmann, 2003) that likely accounted for this pronounced loss of neurofilament in sub-lesional spinal segments. We found a near complete, lamina-specific restoration of neurofilament density in denervated segments of chronically injured rats ($P < 0.01$; Fig. 6B and C).

This result suggested that the SCI led to the formation of new arbors in sub-lesional segments, which we evaluated in more detail with neuronal tract-tracing techniques. We injected a TMR-conjugated antero- and retrograde neuronal tracer into spinal segments L1-L2 (Fig. 6A). We first quantified retrogradely labelled neurons at L6 and found a 2-fold increase in the number of labelled neurons in rats with chronic SCI compared with both intact and subacutely lesioned animals ($P < 0.001$; Fig. 6D and E). We next evaluated the density of anterogradely labelled fibres projecting to L6. The number of labelled fibres at L6 was significantly reduced in the subacute stage ($P < 0.001$), presumably
due to the loss of descending fibres. We observed a 3-fold increase in the density of fibres at L6 in the chronic stage of SCI (P < 0.001; Fig. 6D and E). This increase in fibre density re-established the level of innervation observed in intact rats (P = 0.96; Fig. 6D, right).

To confirm and expand these findings, we next evaluated changes in the density of synapses associated with intraspinal afferent fibres. Glutamate is the most abundant excitatory neurotransmitter in the spinal cord. The vesicular glutamate transporter 2 (vGlut2) is expressed in the synaptic terminals of various spinally projecting supraspinal neurons and intraspinal neurons. Due to the complete interruption of descending pathways after staggered hemisections, vGlut2 is near-exclusively associated with segmental afferents in injured rats (Oliveira et al., 2003; Todd et al., 2003; Alvarez et al., 2004; Landry et al., 2004).

vGlut2-positive fibre endings were primarily found in the superficial dorsal horn and in the intermediate and ventral laminae 7 to 10 (Fig. 7B). Compared with intact rats, we found a significant decrease in vGlut2 density in spinal segment L4 of rats in the subacute stage of the SCI (P < 0.001; Fig. 7A). Rats in the chronic stage of SCI exhibited a near complete, lamina-specific restoration of vGlut2 density (P < 0.01; Fig. 7A and B). These combined results reveal that a striking, lamina-specific reorganization of intraspinal connectivity and associated synaptic terminals spontaneously takes place in the chronic stage of severe SCI.

**Staggered hemisection injury leads to remodelling of sensory terminals within denervated segments**

We sought to investigate whether sensory afferents also undergo remodelling in response to severe SCI. Staining of vesicular glutamate transporter 1 (vGlut1) in the spinal cord mainly identifies the synaptic terminals of corticospinal fibres (Persson et al., 2006), as well as myelinated primary afferents (Oliveira et al., 2003; Todd et al., 2003; Alvarez et al., 2004; Landry et al., 2004), which essentially arise from muscle proprioceptive fibres (Alvarez et al., 2004). Due to the complete interruption of the corticospinal tract after staggered hemisections, vGlut1 staining provides the opportunity to quantify the density of synaptic contacts formed by proprioceptive fibres in denervated spinal segments. vGlut1-positive fibre endings were concentrated in the deep dorsal horn and around the central canal (Fig. 7D), which complemented the distribution pattern of vGlut2-positive synapses. Compared with intact rats, vGlut1 density was significantly reduced in intermediate and ventral laminae in the subacute stage of the SCI (P < 0.01; Fig. 7C). Rats in the chronic stage of SCI showed a density of myelinated primary afferent terminals that did not differ from that observed in intact rats (Fig. 7C). The recovery of vGlut1-positive fibre endings occurred in a lamina-specific manner (Fig. 7D).
Rats with chronic injury show aberrant recruitment of neurons during stepping

We sought to evaluate whether the increased density of fibres and synapses observed in rats with chronic SCI had an impact on the recruitment of sensorimotor circuits during gait execution. To address this question, we studied the expression pattern of the activity-dependent early gene protein c-fos in response to a continuous bout of electrochemically-enabled stepping (Ichiyama et al., 2008; Courtine et al., 2009). Rats in the chronic stage of SCI exhibited a 2-fold increase in the number of c-fos$^{on}$ neurons in motor-related spinal regions (laminae 7 to 10) compared with intact rats ($P < 0.001$; Fig. 8A–C). The number of c-fos$^{on}$ neurons inversely correlated with locomotor capacities ($r = −0.86$, $P < 0.001$; Fig. 8D).

Syndromic analysis establishes relationships between functional and neuromorphological changes after severe injury

We finally aimed at establishing multidirectional correlative relationships between functional, electrophysiological and neuromorphological alterations in chronically injured rats. For this purpose, we applied a syndromic analysis (Ferguson et al., 2013) to all the computed variables ($n = 55$) in order to uncover causal links between neuronal dysfunction and...
compensatory plasticity. The first principal component analysis accounted for 32% of the total variance (Fig. 9). Extraction of PC1 factor loadings revealed that deterioration of stepping capacities, emergence of long-latency reflex responses, and extensor over-activity during electrochemically enabled motor states significantly correlated with injury-induced reorganization of primary afferent and intraspinal axonal systems. This syndromic analysis thus suggested that the aberrant remodelling of lumbosacral circuits significantly contributed to the syndrome of neuronal dysfunction after a severe SCI.

Figure 6 The staggered lateral hemisection SCI led to substantial intraspinal reorganization in the denervated lumbosacral segments. (A) Diagram illustrating anatomical experiments. (B) Bar graph and density plot reporting the overall neurofilament density and lamina-specific neurofilament density within the spinal segment L4 for each experimental group (n = 4–5 rats per group). (C) Representative heatmaps displaying neurofilament density throughout the spinal cord grey matter. (D) Bar graphs reporting the number of retrogradely labelled neurons at L6, and manual fibre counts at L6 after injecting TMR at L1–L2 (n = 5–6 rats per group). (E) Single-slice fibre reconstructions of TMR-labelled fibre density in the right L6 hemicord. **p < 0.01; ***p < 0.001. Error bars, SEM.

(B) Representative heatmaps of vGlut2-positive synaptic terminals. (C) Bar graph and density plot reporting density of vGlut1-positive synaptic terminals in spinal segment L4 (n = 4–5 rats per group). (D) Representative heatmaps of vGlut1-positive synaptic terminals. **p < 0.01; ***p < 0.001. Error bars, SEM.
We show that chronically paralysed rats and humans exhibited similar changes in locomotor activity and reflex behaviour. Using a syndromic analysis (Ferguson et al., 2013) applied on a range of functional, electrophysiological and neuromorphological assessments, we provide statistical evidence that aberrant remodelling of denervated spinal circuits was in part responsible for the development of neuronal dysfunction in the chronic stage of SCI.
Severely paralysed rats and humans exhibit similar neuronal dysfunction in the chronic stage of injury

We aimed at developing a SCI model that shares some of the key pathophysiological and functional features of a severe SCI in humans. Specifically, we sought to create a lesion that induces permanent paralysis, but spares residual bridges of intact neural tissue (Courtine et al., 2008; Murray et al., 2010). We placed a staggered lateral hemisection SCI that met these criteria while providing controlled experimental conditions to assess injury- and intervention-mediated anatomical reorganization (van den Brand et al., 2012). This SCI induced a neuronal dysfunction in the chronic stage of the injury, which contrasted with the progressive recovery of sensorimotor functions that spontaneously occur after partial spinal cord injuries in rodents (Raineteau and Schwab, 2001; Bareyre et al., 2004; Courten et al., 2008), non-human primates (Courtine et al., 2005; Rosenzweig et al., 2010) and humans (Curt et al., 2008).

Neuronal dysfunction in rats was characterized by a premature exhaustion of locomotor muscle activity, which was also observed in chronic, non-ambulatory patients (Dietz and Muller, 2004); and by a dramatic dysfunction of spinal locomotor circuits that we uncovered with the use of an electrochemical neuroprosthesis (Courtine et al., 2009; Musienko et al., 2012). Although the progressive decline of functional capacities has been well documented after a severe SCI (de Leon et al., 1999; Dietz et al., 2002; Bouwenguez et al., 2010) our detailed neurobiomechanical and statistical analyses identified, for the first time, the syndromic signature of deterioration of stepping function in rats. This syndrome included high gait variability, pronounced flexed posture, undesired co-activation between antagonistic muscles, poor interlimb coordination, altered distal joint control, and increased extensor muscle activity during electrochemically enabled locomotion. Comparable changes in gait pattern characteristics have been reported in humans with SCI (Grasso et al., 2004; Lunenburger et al., 2006; McKay et al., 2011). Here, we hypothesized that the development of neuronal dysfunction is largely due to multifaceted plastic changes that propagate throughout local and long-distance interneuronal circuits after severe SCI.

Severely paralysed rats and humans exhibit similar changes in reflex behaviour in the chronic stage of injury

We previously documented the emergence of abnormal long-latency reflex responses in ankle flexor muscles following stimulation of the tibial nerve in non-ambulatory individuals with chronic SCI (Dietz et al., 2009). The amplitude of these reflex responses correlated with the development of neuronal dysfunction (Hubli et al., 2012). These long-latency reflex responses resemble an exacerbation of the flexor reflex afferent response, which plays an important role in the production of locomotion (Busse et al., 1989; Nicol et al., 1995). To date, this syndrome has never been observed in experimental animals with SCI (Dietz et al., 2009). Here, we developed a new model of SCI in which we observed the appearance of abnormal long-latency reflex responses in the chronic stage of the injury. As previously observed in humans (Hubli et al., 2012), the amplitude of long-latency reflexes correlated with the development of neuronal dysfunction in rats with SCI.

These results highlight remarkable similarities in the functional response of the rodent and human spinal cord after the chronic interruption of supraspinal input. The profound reorganization of sub-lesional reflex circuits suggested that a significant anatomical remodelling took place within denervated neuronal networks after severe SCI.

Undirected plasticity of denervated circuits leads to the development of neuronal dysfunction in the chronic stage of injury

Previous investigations in animal models of SCI documented the progressive upregulation of receptor, synapse and fibre density in spinal circuitries deprived of supraspinal input (Krenz and Weaver, 1998; Kitzman, 2006; Bouwenguez et al., 2010; Ichiyama et al., 2011; Kapitza et al., 2012; Tan et al., 2012; Bos et al., 2013). In the present study, we also found a multiplicity of plastic changes in spinal segments caudal to a staggered lateral hemisection SCI. Chronically denervated lumbosacral segments showed sprouting of myelinated primary afferent fibres, increased intraspinal axon density, enhanced bidirectional connectivity between distant spinal segments, and upregulation of the number of glutamatergic synaptic terminals. Using a syndromic analysis (Ferguson et al., 2011, 2013), we established mechanistic relationships between this extensive anatomical reorganization, and the alteration of reflex behaviour and stepping capacities. These results suggested that injury-induced rewiring of denervated spinal segments formed aberrant sensorimotor circuits that caused abnormal reflex responses and recruited inappropriate combinations of neuronal networks during gait execution. Complementary experimental results directly supported this conclusion; analysis of stepping-associated c-fos expression patterns revealed that rats with chronic SCI engaged an abnormally high number of spinal neurons to produce locomotor output.

These combined results reveal that the interruption of supraspinal pathways induces a profound rewiring within denervated spinal segments, which can lead to the formation of aberrant sensorimotor circuits in the chronic stage of the injury. We suggest that these newly established connections misdirect neural information in spinal circuitry during gait execution, which leads to the syndrome of neuronal dysfunction in paralysed rats, and probably in non-ambulatory humans with SCI.

Undirected compensatory plasticity is responsible for the detrimental rewiring of lumbosacral circuits after severe injury

Our results provide overwhelming evidence that a massive reorganization of neural connectivity occurred in denervated spinal
that ameliorates sensorimotor functions (Raineteau and Schwab, 2001; Weidner et al., 2001; Edgerton et al., 2004; Courtine et al., 2008; Rosenzweig et al., 2010). For instance, lamina-specific restoration of serotonergic projections in segments caudal to a moderate SCI has been associated with improved locomotion in rats (Mullner et al., 2008).

In contrast, we show here that after a severe SCI leading to chronic paralysis, the absence of activity leads to a chaotic remodelling of denervated neuronal networks. The resulting undirected compensatory plasticity leads to neuronal dysfunction in the chronic stage of SCI. This potentially detrimental impact of compensatory plasticity has been described in other neural networks, including the autonomic nervous system such as the pyloric network of the stomatogastric ganglion (Nahar et al., 2012). In the spinal cord, the increased expression of constitutively active 5-HT2C receptor isoforms partially compensated for the depletion of brainstem-derived serotonin after severe SCI (Murray et al., 2010). However, the regained excitability in motor neurons contributed to the development of abnormal reflex responses (Murray et al., 2010). Likewise, the depletion of corticospinal tract associated vGlut1 terminals after a pyramidotomy induced a specific sprouting of vGlut1 propriocceptive afferent fibres, but also in this condition, the synaptic reorganization adversely altered proprioceptive reflex circuits (Tan et al., 2012). Although additional mechanisms such as changes in motor neuron network excitability (Lin et al., 2007; Boulenguez et al., 2010) likely contribute to neuronal dysfunction in the chronic stage of SCI, our combined results suggest that undirected compensatory plasticity plays an important role in the emergence of this syndrome.

### Directing compensatory plasticity to improve functional recovery after severe injury

We propose that the myriad of anatomical and functional changes that follow a severe SCI obeys a common biological principle—compensatory plasticity, which is a powerful mechanism to maintain the stability of neurons, and shape the reconfiguration of circuits and pathways following injury (Turrigiano et al., 1998). However, unless this process is directed with use-dependent cues, compensatory plasticity can lead to an aberrant reorganization of denervated spinal circuits, which contributes to the development of neuronal dysfunction in the chronic stage of SCI.

Spinal cord repair interventions primarily focus on developing strategies to promote regeneration of severed neural pathways. The present findings in rats and humans demonstrate that recovery after severe SCI will also necessitate directing and exploiting compensatory plasticity to preserve and improve the functional capacities of denervated spinal sensorimotor circuits (Dietz, 2010). Electrochemically-enabled training is capable of promoting useful remodelling of spinal circuits and functional improvement in severely paralysed rats (Ichiyama et al., 2008, 2011; Courtine et al., 2009; van den Brand et al., 2012). Robotically assisted training also shows efficacy to improve both spinal reflex behaviour and mobility in individuals with incomplete SCI (Hubli et al., 2012). Future studies will need to investigate how activity-based rehabilitation steers compensatory plasticity of spinal sensorimotor circuits in order to prevent, and potentially reverse, the development of neuronal dysfunction after severe SCI.
